#### Introduction

- This talk is an introduction to the formal theory of statistical learning.
- We will introduce the Probably Approximately Correct (PAC) learning model, which was described by Valiant in 1984 following foundational work by Vapnik and Chervonenkis in the 1970s.
- These slides follow the treatment in Understanding Machine Learning by Shai Shalev-Shwartz and Shai Ben-David.

(日)

### The papaya story

- You are on a Pacific Island where papayas are a significant part of the local diet.
- Initial condition: You have never tasted papayas.
- Goal: Learn how to predict whether the papayas you see at the market are tasty or not.
- Features: You will make your predictions based on color and softness, as per your experience with other fruit.

4 日 ト 4 同 ト 4 三 ト 4 三 ト 」

#### A bit more formally...

- We will work with a *domain set X*, which in this case is the set of all possible papayas.
- This set is often a vector of features. In this case a "papaya" is a pair of a color and a softness.
- We also have a *label set Y*, which in this case is {0,1} where 1 means "tasty" and 0 means "not tasty".
- Our experience gives us a training set

$$S = \{(x_1, y_1), \ldots, (x_m, y_m)\}$$

4 □ ▶ 4 同 ▶ 4 Ξ ▶ 4 Ξ ▶

Sac

of pairs in  $X \times Y$ .

For example, ((red, firm), 1) may be a member of S in our case.

# A bit more formally...

- We imagine that we feed all of this information into a (perhaps abstract) machine, our *learner*.
- We would like our learner to output a function

$$h: X \to Y,$$

which we call a *predictor* (or *classifier*).

- This function is supposed to determine whether a papaya with given features is tasty or not.
- In order to understand whether our learner has done a good job, we need to understand how the training set is generated.

## Generating training data

- Assumption #1: The instances (the papayas in this case) are generated by some probability distribution D which is not known to the learner.
- Assumption #2: There exists a "correct" labeling function  $f: X \rightarrow Y$  which is also unknown to the learner.
- The training set S is then generated by choosing the x<sub>i</sub> according to the probability distribution D and the labeling function f which maps the vector of features x<sub>i</sub> to the label y<sub>i</sub>.
- We are now ready to give a formal measure of the success of our learner's predictor.

## Measuring success

- The error of a classifier is the probability that the classifier does not predict the correct label on a random data point generated by the probability distribution D.
- Formally, given an event A ⊂ X we have that D(A) is a number which determines how likely it is to observe some x ∈ A.
- Even more formally, D defines a probability measure on X which assigns to each (measurable) A ⊂ X its measure D(A) ∈ [0, 1].

< □ > < 同 > < 三 > < 三 >

We define the *prediction rule error* of a classifier *h* with given distribution *D* and correct labeling function *f* by

 $L_{D,f}(h) \coloneqq P_{x \sim D}[h(x) \neq f(x)] \coloneqq D(\{x \in X \mid h(x) \neq f(x)\}).$ 

Remember that the only way the learner can interact with the environment is through the training set, so the learner is blind to the underlying distribution *D* and the correct labeling function *f*. In our papayas example, we have just arrived on a new island and have no idea as to how papayas are distributed or how to judge their tastiness before actually eating them.

## A simple learning paradigm: Empirical Risk Minimization

- We now give an example of an algorithm for learning.
- Algorithm input: A training set S, sampled from an unknown distribution D and labeled by some target function f.
- Algorithm output: The function  $h_S: X \to Y$  that minimized the error  $L_{D,f}(h)$  with respect to the unknown D and f.
- Difficulty: We don't know what D and f are, so the true value of L<sub>D,f</sub>(h) is also unknown to us.
- We instead use the *training error*

$$L_{\mathcal{S}}(h) \coloneqq \frac{1}{m} \left| \left\{ i \in [m] \mid h(x_i) \neq y_i \right\} \right|.$$

4 □ ▶ 4 同 ▶ 4 Ξ ▶ 4 Ξ ▶

## A simple learning paradigm: Empirical Risk Minimization

- Since the training sample is the only information about the world available to the learner it makes sense to look for a solution *h*: *X* → *Y* which works well on that data.
- The learning paradigm to generate a predictor h which minimizes L<sub>S</sub>(h) is called Empirical Risk Minimization (ERM).
- It is not obvious how to implement ERM in practice, but we will leave that for another time.

4 日 ト 4 同 ト 4 三 ト 4 三 ト

## Another nightmare: Overfitting

- Consider a new learning task where X := [0,1]<sup>2</sup>, Y := {0,1}, f := 1<sub>x1≤2</sub>, and D is the distribution given by the Lebesgue measure on the square.
- Given any finite training set S we can make a predictor

$$h_S(x) \coloneqq egin{cases} y_i & ext{when } x = x_i ext{ for some } i \in [m] \ 0 & ext{otherwise} \end{cases}$$

- Clearly we have L<sub>S</sub>(h<sub>S</sub>) = 0 so this predictor looks good on our training set.
- However, the true error for such a predictor is

$$L_{D,f}(h_S) = D\left(\left\{x \in [0,1]^2 \mid h_S(x) \neq 1_{x_1 \leq \frac{1}{2}}\right\}\right) = \frac{1}{2}.$$

## Another nightmare: Overfitting

- This situation is not as artificial as it may seem, and it will not always be obvious when a predictor of this form arises in the real world.
- Also, we must consider extremal situations like this when formulating a general approach to a learning task.

< □ > < 同 > < 三 > < 三 >

500

## ERM with inductive bias

- One way to deal with overfitting is by introducing a hypothesis class H ⊂ Y<sup>X</sup> from which will will assume our correct labeling function f: X → Y has been chosen.
- Our ERM learner can then use this additional assumption that f∈ H along with the training set S to make a predictor h: X → Y.
- Ideally H should be chosen appropriately for the problem at hand, but we will come to that another time.

4 日 ト 4 同 ト 4 三 ト 4 三 ト

#### Finite hypothesis class

- The easiest way to restrict the class of hypotheses is by imposing an upper bound on its size.
- It turns out that if H is finite then ERM<sub>H</sub> will not overfit provided that it is based on a sufficiently large training sample as a function of the size of H.
- Given a training set S and correct labeling  $f: X \rightarrow Y$  we choose

 $h_S \in \operatorname{argmin}_{h \in \mathcal{H}} L_S(h),$ 

which is a hypothesis which achieves the minimum value of  $L_S$  over  $\mathcal{H}$ .

▲□▶ ▲□▶ ▲ 三▶ ▲ 三 ▶ ● ● ● ● ●

#### Realizability hypothesis

- We assume there exists some  $h^* \in \mathcal{H}$  such that  $L_{D,f}(h^*) = 0$ .
- This implies that with probability 1 over random samples S we have that  $L_S(h^*) = 0$ .
- This assumption is not very realistic, but it is a good place to start. What we would like to know is the *true risk*  $L_{D.f}(h_S)$ .

4 日 ト 4 同 ト 4 三 ト 4 三 ト 」

Sac

• We now will make a reasonable assumption about the relationship between *D* and *S*.

### The i.i.d. assumption

- We assume the examples in the training set are independent and identically distributed (i.i.d.) according to the probability distribution D.
- The issue here is that L<sub>D,f</sub>(h<sub>S</sub>) depends on a randomly chosen S, so there is a randomness in the choice of the predictor. That is, L<sub>D,f</sub>(h<sub>S</sub>) is a random variable.

(日)

#### Accuracy parameter

- We can never guarantee that the set S we choose will suffice to direct the learner toward a good classifier.
- We also cannot guarantee perfect label prediction, so we introduce the accuracy parameter ε.
- Success is choosing  $h_S$  with  $L_{D,f}(h_S) \le \epsilon$  and failure is choosing  $h_S$  with  $L_{D,f}(h_S) \ge \epsilon$ .
- We can only have L<sub>D,f</sub>(h<sub>S</sub>) > ε if our sample is in the set of misleading examples.

4 日 ト 4 同 ト 4 三 ト 4 三 ト

• One can show that if  $\mathcal{H}$  is a finite hypothesis class,  $\delta \in (0, 1)$ ,  $\epsilon > 0$ , and  $m \in \mathbb{Z}$  satisfies

$$m \geq rac{\log(\left|\mathcal{H}
ight|/\delta)}{\epsilon}$$

then for any labeling function f and any distribution D for which the realizability assumption holds we have that with probability of at least  $1 - \delta$  over the choice of an i.i.d. sample S of size m for every ERM hypothesis  $h_S$  it holds that  $L_{D,f}(h_S) \leq \epsilon$ .

4 □ ▶ 4 同 ▶ 4 Ξ ▶ 4 Ξ ▶

- Typically our hypothesis class  $\mathcal{H}$  will not be finite but we can still obtain a similar result about how many samples we need to take in order to guarantee a choice of ERM hypothesis  $h_S$  it holds that  $L_{D,f}(h_S) \leq \epsilon$  with a probability of at least  $1 \delta$ .
- The key idea is to measure the complexity of the hypothesis class, rather than its size, and we can do this using the notion of VC-dimension.

#### Definition (Restriction of $\mathcal{H}$ to C)

Let  $\mathcal{H}$  be a class of functions from X to  $\{0,1\}$  and let  $C = \{c_1, ..., c_m\} \subseteq X$ . The *restriction of*  $\mathcal{H}$  *to* C is the set of functions from C to  $\{0,1\}$  that can be derived from  $\mathcal{H}$ . That is,

$$\mathcal{H}_{C} = \{(h(c_{1}), ..., h(c_{m})) : h \in H\},\$$

where we represent each function from C to  $\{0,1\}$  as a vector in  $\{0,1\}^{|C|}$ .

#### Definition (Shattering)

A hypothesis class  $\mathcal{H}$  shatters a finite set  $C \subset X$  if the restriction of  $\mathcal{H}$  to C is the set of all functions from C to  $\{0,1\}$ . That is,  $|\mathcal{H}_C| = 2^{|C|}$ .

#### Definition (VC-dimension)

The VC-dimension of a hypothesis class  $\mathcal{H}$ , denoted VCdim( $\mathcal{H}$ ), is the maximal size of a set  $C \subset X$  that can be shattered by  $\mathcal{H}$ . If  $\mathcal{H}$ can shatter sets of arbitrarily large size we say that  $\mathcal{H}$  has infinite VC-dimension.

<u>▲ @ ▶ ▲ 돌 ▶ ▲ 돌 ▶</u>

#### Definition (Uniform convergence)

We say that a hypothesis class  $\mathcal{H}$  has the uniform convergence property (with respect to a domain Z and a loss function  $\ell$ ) when there exists a function  $m_{\mathcal{H}}^{UC}: (0,1)^2 \to \mathbb{N}$  such that for every  $\epsilon, \delta \in (0,1)$  and every probability distribution D over Z we have that if S is a sample of  $m \ge m_{\mathcal{H}}^{UC}(\epsilon, \delta)$  examples drawn i.i.d. according to D then with probability at least  $1 - \delta$  the set S is  $\epsilon$ -representative.

4 日 ト 4 同 ト 4 三 ト 4 三 ト

#### Theorem (The Fundamental Theorem of Statistical Learning)

Let  $\mathcal{H}$  be a hypothesis class of functions from a domain X to  $\{0,1\}$  and let the loss function be the 01 loss. Then, the following are equivalent:

- **1**  $\mathcal{H}$  has the uniform convergence property.
- **2** Any ERM rule is a successful agnostic PAC learner for H.
- 3 H is agnostic PAC learnable.
- 4 *H* is PAC learnable.
- 5 Any ERM rule is a successful PAC learner for H.
- **6** *H* has a finite VC-dimension.

Theorem (The Fundamental Theorem of Statistical Learning (Quantitative Version))

Let  $\mathcal{H}$  be a hypothesis class of functions from a domain X to  $\{0,1\}$  and let the loss function be the 01 loss. Assume that  $VCdim(\mathcal{H}) = d < \infty$ . Then, there are absolute constants  $C_1$ ,  $C_2$  such that:

2

 ${\mathcal H}$  has the uniform convergence property with sample complexity

$$C_1 rac{d + \log(1/\delta)}{\epsilon^2} \leq m_{\mathcal{H}}^{UC}(\epsilon, \delta) \leq C_2 rac{d + \log(1/\delta)}{\epsilon^2}$$

 ${\cal H}$  is agnostic PAC learnable with sample complexity

$$C_1rac{d+\log(1/\delta)}{\epsilon^2}\leq m_{\mathcal{H}}(\epsilon,\delta)\leq C_2rac{d+\log(1/\delta)}{\epsilon^2}$$

3 H is PAC learnable with sample complexity

$$C_1 rac{d + \log(1/\delta)}{\epsilon} \leq m_{\mathcal{H}}(\epsilon, \delta) \leq C_2 rac{d \log(1/\epsilon) + \log(1/\delta)}{\epsilon}$$
